Introduction

This section introduces the divide-and-conquer sorting algorithms, mergesort and quicksort

Also the restricted form of the Master theorem is introduced as well as its application to analyze the running time of mergesort

Quicksort average case analysis is provided

Last, heapsort is described

Properties of sorting algorithms

In place

- Sorting of a data structure does not require any external data structure for storing the intermediate steps
- Selection and insertion sort algorithms are "In place". Merge sort requires intermediary arrays

Stable

If two objects with equal keys appear in the same order in sorted output as they appear in the input array to be sorted

9	3	3'	5	6	5'	2	1	3"	\longrightarrow	Unsorted array
1	2	3	3'	3"	5	5'	6	9	$] \longrightarrow$	Stable
1	2	3'	3	3"	5'	5	6	9	\longrightarrow	Unstable

Basic sorting algorithms

These two algorithms run in $\Theta(n^2)$ using worst case analysis

```
Selection sort(A[1..n])
for i = 1 to n - 1 do
   mini = i : minx = A[i] :
   for i = i + 1 to n do
       if A[i] < minx then
         mini = i : minx = A[i] :
   A[mini] = A[i]; A[i] = minx;
  InsertionSort(A[1..n])
  for (i = 2; i <= n; i + +)
      v = A[i] : i = i-1 :
      while(i > 0 \& A[i] > v)
            A[i+1]=A[i]: i-:
      A[i+1] = v:
```

Merge Sort

Merge sort is a divide-&-conquer sorting algorithm. It works as follow :

- Divide the array to sort in half.
- Recursively sort each half.
- ► Merge the two sorted halves.

Pseudo-code of merge sort is as follows:

```
\begin{aligned} &\mathsf{Mergesort}(A[p..r]) \\ &\mathbf{if} \ p < r \\ &q = \lfloor \frac{p+r}{2} \rfloor \\ &\mathsf{Mergesort}(A[p..q]) \\ &\mathsf{Mergesort}(A[q+1..r]) \\ &\mathsf{Merge}(A,p,q,r) \end{aligned}
```

Merge function

The merge function is a non-recursive component of merge sort which combines 2 sub-arrays already sorted

Takes in input 2 sub-arrays U and V respectively of size m and n and return a sorted array A of size m+n

```
\begin{aligned} &\textit{Merge}(\textit{U}[1..m+1], \textit{V}[1..n+1], \textit{A}[1..m+n])\,;\\ &\textit{i} = \textit{j} = 1; \textit{U}[m+1] = \textit{V}[n+1] = \infty\,;\\ &\textit{for} \  \  (\textit{k} = 1; \textit{k} \leq \textit{m} + \textit{n}; \textit{k} + +)\\ &\textit{if} \  \  \textit{U}[\textit{i}] < \textit{V}[\textit{j}] \  \, \textit{then}\\ &\textit{A}[\textit{k}] = \textit{U}[\textit{i}]\,; \  \textit{i} = \textit{i} + 1\,;\\ &\textit{else}\\ &\textit{A}[\textit{k}] = \textit{V}[\textit{j}]\,; \  \textit{j} = \textit{j} + 1\,; \end{aligned}
```

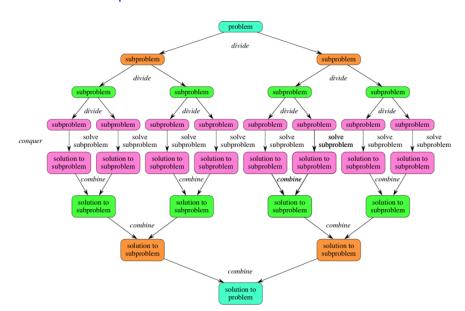

Merge algorithm

```
Merge(U[1..m+1], V[1..n+1], A[1..m+n]);
 i = j = 1; U[m + 1] = V[n + 1] = \infty;
 for (k = 1; k \le m + n; k + +)
      if U[i] < V[j] then
        A[k] = U[i]; i = i + 1;
      else
        A[k] = V[j]; j = j + 1;
                          10
    U=
                                                               \infty
    A=
```

Divide-and-Conquer

Running time of merge sort

The running time of recursive algorithms cannot be analyzed in the same way as iterative algorithms

There are no loops, so summations to count the number of basic operations in loops do not apply for recursive algorithms

Rather recurrence relations will be used to express the number of times basic operations are executed in recursive algorithms

```
Mergesort(A[p..r])

if p < r
q = \lfloor \frac{p+r}{2} \rfloor
Mergesort(A[p..q])
Mergesort(A[q+1..r])
Merge(A, p, q, r)
```

Recurrence relations

The equivalent to polynomial expressions such as $n^2 + 6n + 4$ for iterative algorithms is recurrence relations

A recurrence relation is an equation in which at least one term appears on both sides of the equation such as

$$T(n) = 2T(n-1) + n$$

in which the term T() appears on both side of the equation.

The above recurrence must be read as "the running T(n) on an instance of size n is equal to twice the running time of an instance of size n-1 (i.e. 2T(n-1)) + n"

The recurrence for merge sort

The recurrence relation for merge sort is

```
T(n) = T(\frac{n}{2}) + T(\frac{n}{2}) + O(n)
= 2T(n/2) + O(n)
```

which must be read as "the running time T(n) of merge sort is equal to :

- ightharpoonup the running time of solving two input instances of input size $\frac{n}{2}$ plus
- ▶ the running time of merging two sub-arrays of size n, O(n)"

```
Mergesort(A[p..r])

if p < r
q = \lfloor \frac{p+r}{2} \rfloor
Mergesort(A[p..q])
Mergesort(A[q+1..r])
Merge(A, p, q, r)
```

Merge Sort

```
Mergesort(A[p..r])

if p < r

q = \lfloor \frac{p+r}{2} \rfloor

Mergesort(A[p..q])

Mergesort(A[q+1..r])

Merge(A, p, q, r)
```

The code has two recursive calls, both are executed each time the function is entered

The size of the input is reduced by half each time a recursive call is made

The "dominant" non-recursive term is Merge() which runs $\Theta(n)$

Assuming n is a power of 2, the time T(n) needed to solve an instance of side n is equal to the time to solve two sub-instances of size $\frac{n}{2}$ plus the time $\Theta(n)$ needed to compute Merge():

$$T(n) = 2T(\frac{n}{2}) + n$$

Solving recurrence relations

The recursive terms in a recurrence relation refers to the number of instances creates by the recursive function, it does not indicate directly the computation time, only the non-recursive terms describe the computational time.

In the recurrence T(n) = T(n-1) + 1

- ▶ the recursive term tells there will be n instances of sizes $n, n-1, n-2, \ldots, 2, 1$
- ▶ the non-recursive term describes the computing cost O(1) of each instance, so $\sum_{i=1}^{n} 1 = n$ where i refers to instance i

so the closed form solution to this recurrence is $n \to \Theta(n)$ In the recurrence $T(n) = T(\frac{n}{2}) + 1$

- the recursive term tells there will be $\log n$ instances of sizes $n, \frac{n}{2}, \frac{n}{4}, \dots, 1$
- the non-recursive term describes the computing cost O(1) of each instance, so $\sum_{i=1}^{\log_2 n} 1 = \log n$

so the closed form solution to this recurrence is $\log n \to \Theta(\log n)$

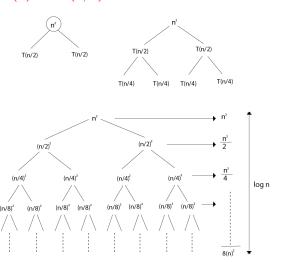

Solving recurrence relations

In the recurrence T(n) = 2T(n/2) + n

- ▶ the recursive term tells there will be $\log n$ instances of different size, 1 instances of size $\frac{n}{4}$, 2 instances of size $\frac{n}{4}$, 4 instances of size $\frac{n}{4}$, etc
- the non-recursive term shows a computing time of n for the first instance, a computing time of $\frac{n}{2}$ for each of the 2 instances of size $\frac{n}{2}$, a computing time of $\frac{n}{4}$ for each of the 4 instances of size $\frac{n}{4}$, ... a computing time of $\frac{n}{n}$ for each of the n instances of size 1
 - ▶ $n \in O(n) + 2\frac{n}{2} \in O(n) + 4\frac{n}{4} \in O(n) + \cdots + n \times 1 \in O(n)$
- ▶ as each level takes O(n) and there are $\log n$ levels, the running time is $n \log n \in \Theta(n \log n)$

Recurrence $T(n) = 2T(n/2) + n^2$

Methods for solving recurrence relations

There exist different techniques to solve recurrence relations :

- ► The Master Theorem
- The substitution method
- ► The recursion tree method

The Master Theorem

The Master Theorem provides closed forms to recurrences of the form :

$$T(n) = aT(\frac{n}{b}) + cn^m$$

for constants $a \ge 1, b > 1, m \ge 0$.

Examples of recurrence relations

$$T(n) = aT(\frac{n}{b}) + cn^m$$

- $a \ge 1, b > 1, m \ge 0$
 - 1. $T(n) = T(\frac{n}{2}) + 1$. Here a = 1, b = 2, m = 0.
 - 2. T(n) = 2T(n/2) + n. Here a = 2, b = 2, m = 1.
 - 3. $T(n) = T(\sqrt{n}) + n$. Recurrence does not satisfies de conditions for master theorem, b is undefined
 - 4. T(n) = T(n/3) + T(2n/3) + n. Recurrence does not satisfies conditions for master theorem. Two recursive terms, each with a different b: 1-b=3 and 2-b=3/2

The Master Theorem

$$T(n) = aT(\frac{n}{b}) + cn^m$$

A solution to a recurrence of the above form (its closed form) is determined by the values of the constants a, b and m

$$T(n) \in \begin{cases} \Theta(n^m) & \text{if } a < b^m; \\ \Theta(n^m \log n) & \text{if } a = b^m; \\ \Theta(n^{\log_b a}) & \text{if } a > b^m. \end{cases}$$

This formulation is sometime refereed as the "restricted" form of the Master Theorem

Example 1

Give the exact order of the recurrence

$$T(n)=2T(\frac{n}{2})+n$$

Here a = 2, b = 2 and m = 1.

We have $a = 2 = b^m = 2^1 = 2$, therefore the case that applies is $a = b^m$.

Consequently, $T(n) \in \Theta(n^m \log n) = \Theta(n \log n)$.

Example 2

Give the exact order of the recurrence

$$T(n) = 6T(\frac{n}{4}) + n^2$$

Here a = 6, b = 4 and m = 2.

We have $a = 6 < b^m = 4^2 = 16$, therefore the case that applies is $a < b^m$.

Consequently, $T(n) \in \Theta(n^m) = \Theta(n^2)$.

Example 3

Give the exact order of the recurrence

$$T(n) = 7T(\frac{n}{2}) + n^2$$

Here a = 7, b = 2 and m = 2.

We have $a = 7 > b^m = 2^2 = 4$, therefore the case that applies is $a > b^m$.

Consequently, $T(n) \in \Theta(n^{\log_b a}) = \Theta(n^{\log_2 7})$.

Exercise

Not all the recurrences can be solved using the Master Theorem. Among the following recurrences which one you think can be solved using the Master Theorem?

a)
$$T(n) = 2T(n/2) + n^4$$

b)
$$T(n) = T(7n/10) + n$$

c)
$$T(n) = 16T(n/4) + n^2$$

d)
$$T(n) = 7T(n/3) + n^2$$

e)
$$T(n) = 7T(n/2) + n^2$$

f)
$$T(n) = 3T(n/4) + \sqrt{n}$$

g)
$$T(n) = T(n-2) + n^2$$

h)
$$T(n) = 4T(n/3) + n \log n$$

i)
$$T(n) = 3T(n/3) + \frac{n}{\log n}$$

k)
$$T(n) = 4T(n/2) + n^2\sqrt{n}$$

1)
$$T(n) = 3T(n/3 - 2) + \frac{n}{2}$$

m)
$$T(n) = 2T(n/2) + \frac{n}{\log n}$$

n)
$$T(n) = \sqrt{n}T(\sqrt{n}) + n$$

o)
$$T(n) = T(n-2) + \log n$$

Solving the recurrence for Merge sort

Computing $q = \lfloor \frac{p+r}{2} \rfloor$ cost O(1). Merge is in O(n), thus m = 1.

Mergesort does exactly 2 recursive calls, thus a = 2.

The input to the recursive calls have size $\frac{n}{2}$, thus b = 2.

The recurrence relation for merge sort is :

$$T(n) = \begin{cases} 1 & \text{when } n = 1 \\ 2T(n/2) + O(n) & \text{otherwise} \end{cases}$$

Solving this recurrence using Master theorem, the case that applies is $a = b^m$.

Consequently, the running time of merge sort $T(n) \in \Theta(n^m \log n) = \Theta(n \log n)$.

Quicksort

Another divide-and-conquer sorting algorithm

An array A[p..r] of integers is partitioned into two subarrays A[p..q] and A[q+1..r]

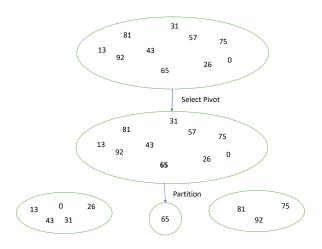

▶ such that the elements in A[p..q] are less than all elements in A[q+1..r]

The subarrays are recursively sorted by calls to quicksort

Quicksort Code

```
 \begin{aligned} &\text{Quicksort}(\mathsf{A},\ \mathsf{p},\ \mathsf{r}) \\ &\text{if } (\mathsf{p} < \mathsf{r})\ /^* \text{ the array has at least 2 elements */} \\ &q = \mathsf{Partition}(\mathsf{A},\ \mathsf{p},\ \mathsf{r})\,;\ /^*\ \mathsf{q} \text{ is the index in A of the pivot element */} \\ &\text{Quicksort}(\mathsf{A},\ \mathsf{p},\ \mathsf{q}\text{-}1)\,; \\ &\text{Quicksort}(\mathsf{A},\ \mathsf{q}\text{+}1,\ \mathsf{r})\,; \end{aligned}
```

Quicksort idea

After partition, the pivot is in its right position in a sorted array. Quicksort is recursively applied to the next two subarrays.

Partition

```
 \begin{aligned} & \text{Quicksort}(A, \, p, \, r) \\ & \text{if} \, \left(p < r\right) \\ & \text{q} &= \text{Partition}(A, \, p, \, r) \, ; \\ & \text{Quicksort}(A, \, p, \, q\text{-}1) \, ; \\ & \text{Quicksort}(A, \, q\text{+}1, \, r) \, ; \end{aligned}
```

- ► All the action takes place in the partition() function which rearranges the subarray
- End result : Two subarrays, all values in first subarray < all values in second
- Returns the index of the "pivot" element separating the two subarrays

Partition code

Partition() takes in input the array A and the section between indexes p and r to partition

 ${f x}$ is the pivot element, in this code the last element in the array is selected as pivot

Partition() returns the index in A of the pivot element once partition is completed

The position of the pivot element will never be part of a sub-array to partition, it is at its right position in the sorted array

```
\begin{aligned} & \text{Partition}(A, \, p, \, r) \\ & \times = A[r] \, ; \\ & \text{i} = p - 1 \, ; \\ & \text{for} \, (j = p \, ; \, j < r \, ; \, j + +) \\ & \text{if} \, (A[j] \leq x) \\ & \text{i} = \text{i} + 1 \, ; \\ & \text{swap}(A[i], A[j]) \, ; \\ & \text{swap}(A[i+1], A[r]) \, ; \\ & \text{return} \, \text{i} + 1 \, ; \end{aligned}
```

Example with running partition()

```
p,i j r
2 8 7 1 3 5 6 4
(c)
   (d)
(e)
(f)
(g)
(h)
(i)
```

```
\begin{split} & \mathsf{Partition}(A,\, p,\, r) \\ & \times = A[r]\,; \\ & \mathsf{i} = \mathsf{p} \cdot 1\,; \\ & \mathsf{for}\; (\mathsf{j} = \mathsf{p}\,;\, \mathsf{j} < r\,;\, \mathsf{j} + +) \\ & \mathsf{if}\; (A[\mathsf{j}] \le \mathsf{x}) \\ & \mathsf{i} = \mathsf{i} + 1\,; \\ & \mathsf{swap}(A[\mathsf{i} + 1], A[\mathsf{j}])\,; \\ & \mathsf{swap}(A[\mathsf{i} + 1], A[\mathsf{r}])\,; \\ & \mathsf{return}\; \mathsf{i} + 1\,; \end{split}
```

Performance of Quicksort

Quicksort calls itself on 2 sub-arrays with likely different sizes. The asymptotic running time of Quicksort depends on how these two sub-arrays are balanced

$$T(n) = T(L) + T(R) + O(n)$$

where L and R are the number of elements in each sub-array.

- ▶ If the subarrays are balanced, then quicksort can run as fast as merge sort.
- If they are unbalanced, then quicksort can run as slowly as insertion sort.

Worst case analysis of Quicksort

Occurs when the subarrays are completely unbalanced for each recursive call. Has 0 element in one subarray and n-1 elements in the other subarray. The recurrence is

$$T(n) = T(n-1) + T(0) + O(n)$$
 (1)

$$= T(n-1) + O(n)$$
 (2)

This recurrence cannot be solved using the Master theorem, but can be solved using the substitution method or the recursion tree method (will see them later)

Intuitively, since only element of the array is sorted properly at each recursive call (the pivot element), the input size reduces only by 1, thus n-1 recursive calls are made.

Each recursive call entails a call to partition() which runs in O(n), thus the worst case running time of Quicksort is $O(n^2)$

```
 \begin{aligned} & \text{Quicksort}(A, \, p, \, r) \\ & \text{if} \, (p < r) \\ & q = \text{Partition}(A, \, p, \, r) \, ; \\ & \text{Quicksort}(A, \, p, \, q\text{-}1) \, ; \\ & \text{Quicksort}(A, \, q\text{+}1, \, r) \, ; \end{aligned}
```

Best case of Quicksort

Occurs when the subarrays are completely balanced every time.

Each subarray has $\leq n/2$ elements.

The recurrence is

$$T(n) = T(n/2) + T(n/2) + O(n)$$
 (3)

$$= 2T(n/2) + O(n) (4)$$

This recurrence can be solved using the master theorem method.

As we already know, the solution of this recurrence is $T(n) \in \Theta(n \log n)$

Quicksort well designed

It is easy to avoid the worst case performance for quicksort.

Your textbooks introduces two possible solutions to this issue :

- Randomize the input, or
- Pick a random pivot element

This solve the bad worst-case behavior because no particular input can be chosen that makes quicksort runs in $O(n^2)$

Analyzing quicksort : effects of partitioning

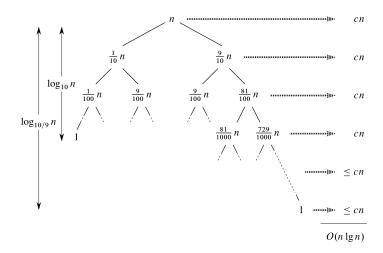

- Imagine that Partition always produces a 9-to-1 split.
- Get the recurrence :

$$T(n) \leq T(9n/10) + T(n/10) + O(n)$$

= $O(n \log n)$

See the recurrence tree in the next slide, the number of levels of the partitioning is $\log_{\frac{10}{9}} n$, local work at each level cost no more than cn, therefore quicksort runs in $O(n \log n)$ even for this bad partitioning

Analysing quicksort : effects of partitioning

We need to consider all the possible inputs of size n that can be submitted to a quicksort routine.

These are the n possible ways that "partition" can split an array into 2 sub-arrays : 0: n-1; 1: n-2; 2: n-3; ..., n-1: 0

Assumptions : all splits equally likely to occur, thus, each split has probability 1/n to occur

The recurrence relation is the following:

$$T(n) = \frac{1}{n} \left(\sum_{k=0}^{k=n-1} T(k) + T(n-1-k) \right) + O(n)$$

Since $\sum_{k=0}^{k=n-1} T(k) = \sum_{k=0}^{k=n-1} T(n-1-k)$, T(n) can be written as

$$\frac{2}{n}\sum_{k=0}^{k=n-1}T(k)+O(n)$$

- We can solve this recurrence using the substitution method
- Guess the answer $T(n) = O(n \lg n)$
- Assume that the inductive hypothesis holds
 - $T(n) \le cn \log n$ for some constant c
- Substitute it in for some value < n</p>
 - ► The value k in the recurrence

Prove that it follows for n

$$T(n) = \frac{2}{n} \sum_{k=0}^{k=n-1} T(k) + O(n)$$

$$\leq \frac{2}{n} \sum_{k=0}^{k=n-1} (ck \log k) + O(n) \text{ inductive hypothesis}$$

$$= \frac{2c}{n} \sum_{k=0}^{k=n-1} k \log k + O(n)$$

$$\leq \frac{2c}{n} \left(\frac{1}{2}n^2 \log n - \frac{1}{8}n^2\right) + O(n)$$

The summation $\sum_{k=1}^{k=n-1} k \log k$ can be bound above by $\frac{1}{2}n^2 \log n - \frac{1}{8}n^2$ but this is not proved here.

$$T(n) \leq \frac{2c}{n} \left(\frac{1}{2} n^2 \log n - \frac{1}{8} n^2 \right) + O(n)$$

$$= cn \log n - \frac{c}{4} n + O(n)$$

$$= cn \log n + \left(O(n) - \frac{c}{4} n \right)$$

$$= cn \log n \text{ for } c \text{ such that } \frac{cn}{4} > O(n)$$

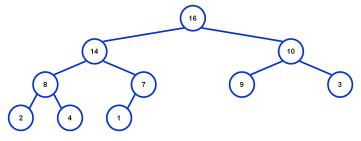

Thus $T(n) \in O(n \log n)$

Sorting

- So far we have seen different sorting algorithms such as selection sort, and insertion, and merge sort and quicksort
 - Merge sort runs in $O(n \log n)$ both in best, average and worst-case
 - Insertion/selection sort run in $O(n^2)$, but insertion sort is fast when array is nearly sorted, runs fast in practice
- ▶ Next on the agenda : Heapsort
- Prior to describe heapsort, we introduce the heap data structure and operations on that data structure

Heap: definition

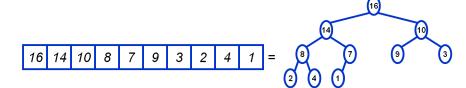

► A heap is a complete binary tree

- Binary because each node has at most two children
- Complete because each internal node, except possibly at the last level, has exactly two children

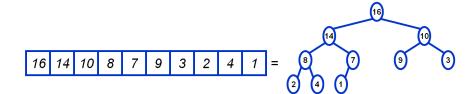

Heaps

▶ In practice, heaps are usually implemented as arrays

Heaps

- How to represent a complete binary tree as an array :
 - ightharpoonup The root node is A[1]
 - Ordering nodes per levels starting at the root, and from left to right in a same level, then node i is A[i]
 - ► The parent of node i is $A[\lfloor i/2 \rfloor]$
 - ► The left child of node *i* is *A*[2*i*]
 - ▶ The right child of node *i* is A[2i + 1]

Referencing Heap Elements

```
function Parent(i)
  return [i/2];

function Left(i)
  return 2 × i;
```

```
function Right(i)
return 2 × i + 1;
```

The Heap Property

► Heaps must satisfy the following relation :

$$A[Parent(i)] \ge A[i]$$
 for all nodes $i > 1$

► In other words, the value of a node is at most the value of its parent

Heap Height

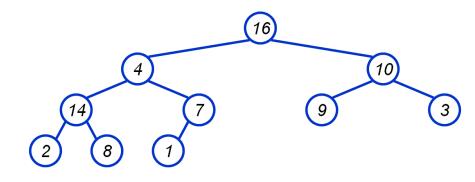

- ► The height of a node in the tree = the number of edges on the longest downward path to a leaf
- ▶ The height of a tree = the height of its root
- ▶ What is the height of an n-element heap? Why?
- ► Heap operations take at most time proportional to the height of the heap

Heap Operations

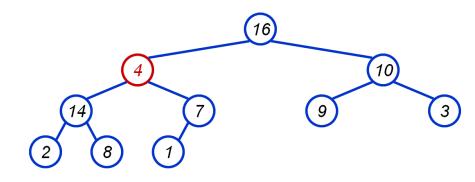

There are two main heap operations : heapify and buildheap.

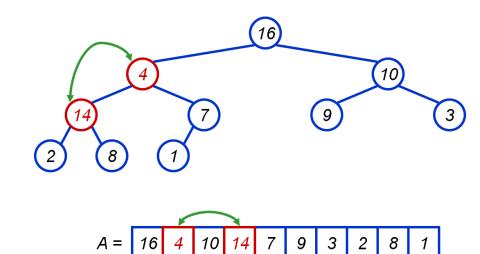

Heapify(): restore the heap property:

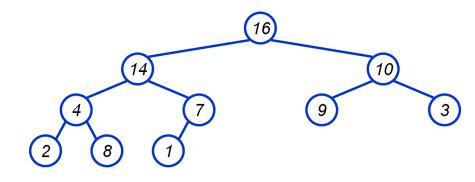

- Consider node i in the heap with children I and r
- Nodes I and r are each the root of a subtree, each assumed to be a heap
- Problem : Node i may violate the heap property
- ➤ Solution : let the value of node *i* "float down" in one of its two subtrees until the heap property is restored at node *i*

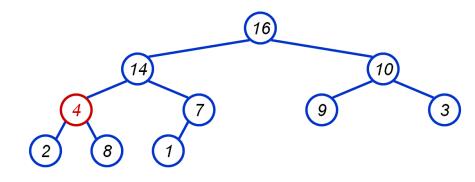

A = 16 4 10 14 7 9 3 2 8 1

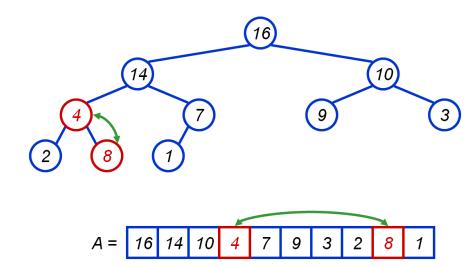

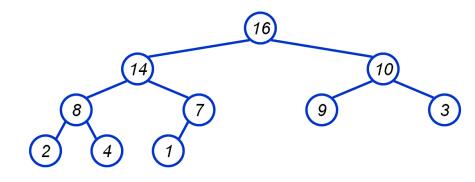

A = 16 14 10 4 7 9 3 2 8 1

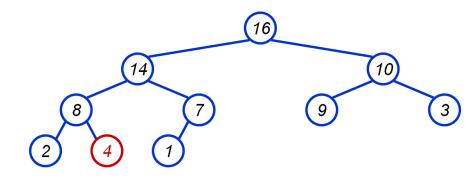

A = 16 14 10 4 7 9 3 2 8 1

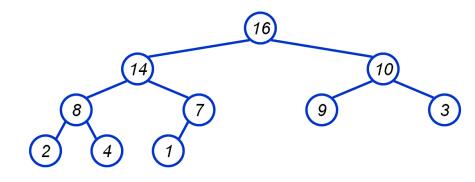

A = 16 14 10 8 7 9 3 2 4 1

A = 16 14 10 8 7 9 3 2 4 1

Algorithm for heapify

An array A[], where heap_size(A) returns the dimension of A

```
Heapify(A, i)
  I = Left(i); r = Right(i);
  if (I \leq heap\_size(A) \& A[I] > A[i])
    largest = 1:
  else
    largest = i;
  if (r \le heap\_size(A) \& A[r] > A[largest])
    largest = r:
  if (largest != i)
    Swap(A, i, largest);
    Heapify(A, largest);
```

Example: heapify

This array $A = \begin{bmatrix} 23, 11, 14, 9, 13, 10, 1, 5, 7, 12 \end{bmatrix}$ is not a heap as Parent(5) = $\lfloor \frac{i}{2} \rfloor = 2$, A[2] = 11 in the array, which violates the max-heap property as A[5] = 13 is greater than A[2].

Call heapify(A,2) which swap A[2] with Right(2) = 2i + 1 = A[5]

$$A = [23, 13, 14, 9, 11, 10, 1, 5, 7, 12]$$

Left(5) = 10 and A[10] > A[5] which violates the heap property $A[Parent(i)] \ge A[i]$. Thus heapify continues, swap A[5] with Left(5) = 2i = A[10]

$$A = [23, 13, 14, 9, 12, 10, 1, 5, 7, 11]$$

Analyzing Heapify()

- Number of basic operations performed before calling itself?
- How many times can Heapify() recursively call itself?
- What is the worst-case running time of Heapify() on a heap of size n?

Analyzing Heapify()

- The work done in each line of Heapify() is ⊖(1) except for the rucursive call
- ▶ If the heap at *i* has *n* elements, how many elements can the subtrees at *l* or *r* have? Answer : at most 2n/3 (worst case : bottom row 1/2 full)
- So time taken by Heapify() is given by the recurrence

$$T(n) \leq T(2n/3) + \Theta(1)$$

► Restricted Master Theorem applies : a = 1, b = 3/2, m = 0. We have $a = b^m = \frac{3}{2}^0 = 1$, which corresponds to case $\Theta(n^m \log n) = \Theta(n^0 \log n) = \Theta(\log n)$, thus

$$T(n) \in \Theta(\log n)$$

Heap Operations : BuildHeap()

- We can build a heap in a bottom-up manner by running Heapify() on successive subarrays
 - Note: for array of length n, all elements in range $A[(\lfloor n/2 \rfloor + 1)..n]$ are heaps (Why?)
 - ▶ Walk backwards through the array from $\lfloor n/2 \rfloor$ to 1, calling Heapify() on each node.
- given an unsorted array A, make A a heap

```
BuildHeap(A)

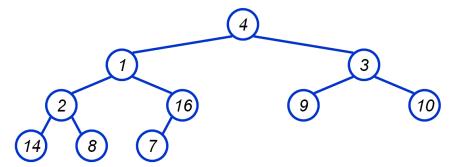

heap_size(A) = length(A);

for (i = \lfloor length(A)/2 \rfloor downto 1)

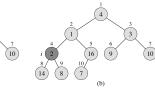

Heapify(A, i);
```

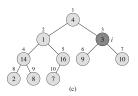

BuildHeap() Example

Work through example A = [4, 1, 3, 2, 16, 9, 10, 14, 8, 7]

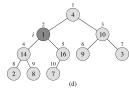

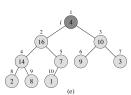

A 4 1 3 2 16 9 10 14 8 7

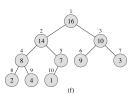

(a)

BuildHeap: a second example

```
Run the algorithm BuildHeap(A) on the array A = [5, 3, 17, 10, 84, 19, 6, 22, 9]
Find i = \lfloor \frac{length(A)}{2} \rfloor = \lfloor \frac{9}{2} \rfloor = 4, the entry in A where BuildHeap starts
BuildHeap starts at A[4], from which heapify is run. Left(4) = 8, A[8] = 10;
Right(4) = 9, A[9] = 9, so nothing to change
Next A[3] = 17, Left(3) = 6, A[6] = 19; Right(3) = 7, A[7] = 6. A[6] > A[3], so
heapify is needed on A[3], yielding
A[5, 3, 17, 22, 84, 19, 6, 10, 9]
A[5, 3, 19, 22, 84, 17, 6, 10, 9]
Next A[2] = 3, and so on
A[5, 84, 19, 22, 3, 17, 6, 10, 9]
A[84, 5, 19, 22, 3, 17, 6, 10, 9]
A[84, 22, 19, 5, 3, 17, 6, 10, 9]
A[84, 22, 19, 10, 3, 17, 6, 5, 9]
```

Analyzing BuildHeap()

- ▶ Each call to Heapify() takes $O(\log n)$ time
- ▶ There are O(n) such calls (specifically, $\lfloor n/2 \rfloor$)
- ▶ Thus the running time is $O(n \log n)$
 - Is this a correct asymptotic upper bound?
 - Is this an asymptotically tight bound?
- ► A tighter bound is O(n)

Analyzing BuildHeap(): Tight

Heap-properties of an n-element heap

- ightharpoonup Height = $\lfloor \log n \rfloor$
- At most $\lceil \frac{n}{2^{h+1}} \rceil$ nodes of any height h
- ▶ The time for Heapify on a node of height h is O(h)

$$\sum_{h=0}^{\lfloor \log n \rfloor} \lceil \frac{n}{2^{h+1}} \rceil O(h) = O(n \sum_{h=0}^{\lfloor \log n \rfloor} \frac{h}{2^h})$$
$$= O(n \sum_{h=0}^{\infty} \frac{h}{2^h})$$
$$= O(n)$$

Analyzing BuildHeap() : Tight

$$\sum_{h=0}^{\infty} \frac{h}{2^h} = \sum_{h=0}^{\infty} h(\frac{1}{2})^h$$

$$= \sum_{h=0}^{\infty} hx^h \text{ where } x = \frac{1}{2}$$

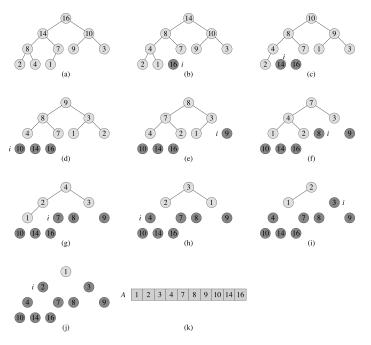

$$= \frac{1/2}{(1-\frac{1}{2})^2} \text{ the closed form of } \sum_{h=0}^{\infty} h(\frac{1}{2})^h$$

$$= 2$$

Heapsort

- Given BuildHeap(), a sorting algorithm is easily constructed :
 - Maximum element is at A[1]
 - Swap A[1] with element at A[n], A[n] now contains correct value
 - Decrement heap_size[A]
 - Restore heap property at A[1] by calling Heapify()
 - Repeat, always swapping A[1] for A[heap_size(A)]

```
\label{eq:heapsort} \begin{split} & \text{Heapsort}(A) \\ & \text{BuildHeap}(A) \,; \\ & \text{for } (i = \text{length}(A) \text{ downto } 2) \\ & \text{Swap}(A[1], A[i]) \,; \\ & \text{heap\_size}(A) = \text{heap\_size}(A) - 1 \,; \\ & \text{Heapify}(A, 1) \,; \end{split}
```

Analyzing Heapsort

- ▶ The call to BuildHeap() takes O(n) time
- ► Each of the n 1 calls to Heapify() takes $O(\log n)$ time
- Thus the total time taken by HeapSort()

$$= O(n) + (n-1)O(\log n)$$

$$= O(n) + O(n \log n)$$

$$= O(n \log n)$$

Note, like merge sort, the running time of heapsort is independent of the initial state of the array to be sorted. So best case and average case of heapsort are in $O(n \log n)$

Priority Queues

- ▶ Heapsort is a nice algorithm, but in practice Quicksort is faster
- ▶ But the heap data structure is useful for implementing priority queues :
 - ► A data structure like queue or stack, but where a value or key is associated to each element, representing the priority of the corresponding element. The element with the highest priority is served first
 - Supports the operations Insert(), Maximum(), and ExtractMax()

Priority Queue Operations

- function Insert(S, x) inserts the element x into set S
- ► **function** Maximum(S) returns the element of S with the maximum key
- ► **function** ExtractMax(S) removes and returns the element of S with the maximum key
- Think how to implement these operations using a heap?

Priority queue: extracting the max element

```
\begin{split} &\mathsf{ExtractMax}(\mathsf{A}) \\ &\mathsf{max} = \mathsf{A}[1] \\ &\mathsf{A}[1] = \mathsf{A}[\mathsf{A}.\mathsf{heap}\text{-size}] \\ &\mathsf{A}.\mathsf{heap}\text{-size} = \mathsf{A}.\mathsf{heap}\text{-size} \text{-}1 \\ &\mathsf{Heapify}(\mathsf{A},1) \\ &\mathsf{return} \ \mathsf{max} \end{split}
```

Since Heapify runs in $\log n$, extracting the largest element of a priority queue based on a heap takes $\log n$

Priority queue: inserting an element

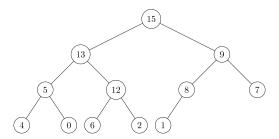

```
\begin{split} &\mathsf{Insert}(\mathsf{A}, \, \mathsf{key}) \\ &\mathsf{A}.\mathsf{heap\text{-}size} = \mathsf{A}.\mathsf{heap\text{-}size} + 1 \\ &\mathsf{A}[\mathsf{A}.\mathsf{heap\text{-}size}] = \mathsf{key} \\ &\mathsf{i} = \mathsf{A}.\mathsf{heap\text{-}size} \\ &\mathsf{while} \; \mathsf{i} > 1 \; \mathsf{and} \; \mathsf{A}[\mathsf{Parent}(\mathsf{i})] < \mathsf{A}[\mathsf{i}] \\ &\mathsf{swap}(\mathsf{A}[\mathsf{i}], \, \mathsf{A}[\mathsf{Parent}(\mathsf{i})]) \\ &\mathsf{i} = \mathsf{Parent}(\mathsf{i}) \end{split}
```

The number of iterations execute by the while loop is bound above by $\log n$, therefore inserting an element of a priority queue based on a heap takes $\log n$

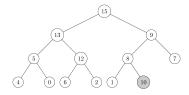

Example: Inserting an element

Insert (A, 10) on the heap A = [15, 13, 9, 5, 12, 8, 7, 4, 0, 6, 2, 1]

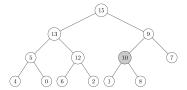

► Original heap

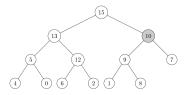

Add the key 10 to the next position in the heap (corresponding to a new entry extending the array A).

▶ Since the parent key is smaller than 10, the nodes are swapped

▶ Since the parent key is smaller than 10, the nodes are swapped

Solving recurrence relations : Recursion tree method

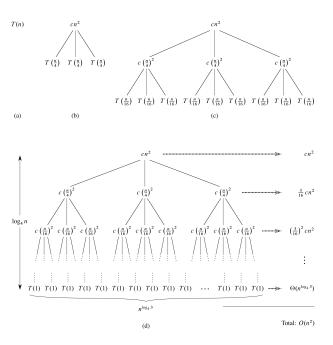

To analyze the recurrence by using the recursion tree, we will

- draw a recursion tree with cost of single call at each node
- ► find the running time at each level of the tree by summing the running time of each call at that level
- find the number of levels
- Last, the running time is sum of costs in all nodes

Example of a recurrence relation :

$$T(n) = 3T(\lfloor n/4 \rfloor) + cn^2.$$

Analysis

Number of levels in the tree :

The number of levels in the tree depends by how much subproblem sizes decrease

$$T(n) = 3T(\lfloor n/4 \rfloor) + cn^2.$$

In this example, the subproblem sizes decrease by a factor of 4 at each new level

The last level is where the size of each subproblem =1, i.e. when $n/4^i=1$

Therefore the number of levels is $i = \log_4 n$.

Analysis

Number of nodes at each level of the tree :

$$T(n) = 3T(\lfloor n/4 \rfloor) + cn^2.$$

From the recurrence we can see the number of nodes at level i is 3 times the number of nodes at level i-1

In terms of level 0, the number of nodes at level $i \ge 0$ is 3^i

- level $0 = 3^0 = 1$
- level $1 = 3^1 = 3$
- level $\log_4 n = 3^{\log_4 n} = n^{\log_4 3}$ (using the rule $a^{\log b} = b^{\log a}$)

Running time

According to the recurrence relation the number of basic operations executed at level 0 is cn^2 (given the input size = n)

At level 1, the input size of each subproblem is $\lfloor \frac{n}{4} \rfloor$, therefore the number of basic operations executed by each subproblem is $c(\lfloor \frac{n}{4} \rfloor)^2$

Assuming n is a power of 2, the number of basic operations is $c(\frac{n}{4})^2$. Since there are 3 subproblems, the running time is the sum of the running time of each node, i.e. $c(\frac{3n}{4})^2$ or $\frac{3}{16}cn^2$

At level *i*, the running time is also the sum of the running time of each node at level *i*, i.e. $(\frac{3}{16})^i cn^2$

Running time

As the number of levels is $log_4 n$, the summation of the running time of each level is

$$T(n) = cn^{2} + \frac{3}{16}cn^{2} + (\frac{3}{16})^{2}cn^{2} + \dots + (\frac{n}{16})^{\log_{4}(n-1)}cn^{2} + cn^{\log_{4}3}$$

$$= cn^{2} \left[1 + \frac{3}{16} + (\frac{3}{16})^{2} + \dots + (\frac{3}{16})^{\log_{4}(n-1)} \right] + cn^{\log_{4}3}$$

$$= O(n^{2})$$

The last step is a decreasing geometric series (each terms multiplied by $\frac{1}{3}$), which converges to $\frac{16}{13}$

Exercise

Use the recursion tree method to find a good asymptotic upper bound on the recurrence $T(n) = 2T(n/2) + n^2$

The number of terms in the summation = number of levels in the tree = log_2n . More precisely,

$$T(n) = n^{2} + \frac{1}{2}n^{2} + \frac{1}{4}n^{2} + \dots + \frac{1}{2^{\log n}}n^{2}$$

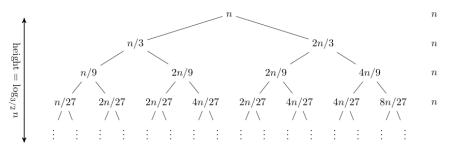

$$= n^{2} \left[1 + \frac{1}{2} + \frac{1}{4} + \dots + \frac{1}{2^{\log n}} \right]$$

$$= O(n^{2})$$

 $\frac{1}{2} + \frac{1}{4} + \cdots + \frac{1}{2^{\log n}}$ is a geometric series that converges to 1

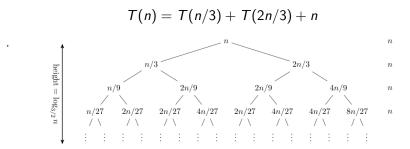

Exercise

Use a recursion tree to determine a good asymptotic upper bound on the recurrence T(n) = T(n/3) + T(2n/3) + n.

Each node at level i expands into 2 nodes at level i+1

Exercise 3: number of levels

The input size of the node on the left is $\frac{n}{3}$, while the size of the other node is $\frac{3n}{2}$

The input size decreases much faster on the left than on the right side

Exercise 3: number of levels

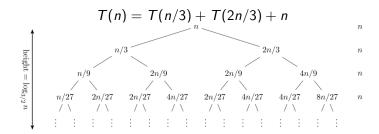

The number of levels of the leftmost path (the shortest path) is $\log_3 n$

The number of levels on the rightmost path (the longest one) is $\log_{3/2} n$ (as $\frac{2n}{3} = \frac{n}{3/2}$)

The number of levels in the other branches are a mix of these two extremes

Exercise 3: running time

The longest branch of the tree has $log_{3/2} n$ levels

At each level *n* basic operations are executed

 $n \times \log_{3/2} n$ is in $O(n \log n)$ as logs from different bases differ only by a constant multiplicative factor

General form of the Master Theorem

General Master Theorem : Let constants $a \ge 1, b > 1$, and ϵ be a strictly positive real number. Assume that T(n) satisfies the recurrence relation

$$T(n) = aT(\frac{n}{b}) + f(n),$$

Then T(n) has the following asymptotic bounds :

$$T(n) \in \left\{ \begin{array}{ll} \Theta(n^{\log_b a}) & \text{ if } f(n) \in O(n^{\log_b a - \epsilon}); \\ \Theta(f(n) \log n) & \text{ if } f(n) \in \Theta(n^{\log_b a}); \\ \Theta(f(n)) & \text{ if } f(n) \in \Omega(n^{\log_b a + \epsilon}) \text{ and } af(n/b) \leq cf(n) \\ & \text{ for some } c < 1 \text{ and } n \text{ large enough.} \end{array} \right.$$

General vs restricted Master Theorem

This form of the Master Theorem is called "general" because f(n) can be any function, it is not restricted to n^m .

$$T(n) \in \left\{ \begin{array}{ll} \Theta(n^{\log_b a}) & \text{ if } f(n) \in O(n^{\log_b a - \epsilon}); \\ \Theta(f(n) \log n) & \text{ if } f(n) \in \Theta(n^{\log_b a}); \\ \Theta(f(n)) & \text{ if } f(n) \in \Omega(n^{\log_b a + \epsilon}) \text{ and } af(n/b) \leq cf(n) \\ & \text{ for some } c < 1 \text{ and } n \text{ large enough.} \end{array} \right.$$

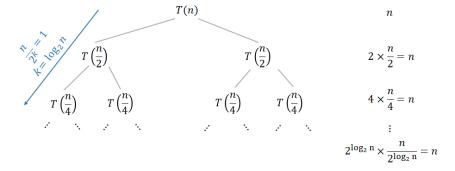

The general form can be of course applied to recurrences in the form $T(n) = aT(\frac{n}{b}) + cn^m$ but with the restricted form it easier to identify the exact order of a recurrence

$$T(n) \in \begin{cases} \Theta(n^m) & \text{if } a < b^m; \\ \Theta(n^m \log n) & \text{if } a = b^m; \\ \Theta(n^{\log_b a}) & \text{if } a > b^m. \end{cases}$$

$$T(n) = 2T(n/2) + n$$

The recursive term has the same asymptotic running time at each level as the non-recursive term. Thus, both terms are in the same complexity class :

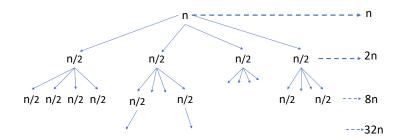

- 1. $\rightarrow f(n) \in \Theta(n^{\log_b a})$
- 2. $\Rightarrow T(n) \in \Theta(f(n) \log n)$

$$T(n) = 4T(n/2) + n$$

The amount of computation performs by the recursive term 4T(n/2) at each level is greater than f(n) = n. Thus the running time of the non-recursive term is bound above by $n^{\log_b a - \epsilon} \Rightarrow O(n^{\log_b a - \epsilon})$

- 1. $\rightarrow f(n) \in O(n^{\log_b a \epsilon})$
- 2. $\Rightarrow T(n) \in \Theta(n^{\log_b a})$

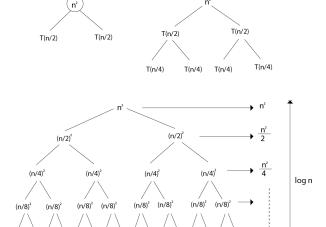

6

$$T(n) = 2T(n/2) + n^2$$

The amount of computation performs by the recursive term 2T(n/2) at each level is smaller than $f(n) = n^2$. Thus the running time of the non-recursive term is bound below by $n^{\log_b a + \epsilon} \Rightarrow \Omega(n^{\log_b a + \epsilon})$

- 1. $\rightarrow f(n) \in \Omega(n^{\log_b a + \epsilon})$
- 2. $\Rightarrow T(n) \in \Theta(f(n))$

Use the general Master Theorem to give the exact order of the recurrence

$$T(n) = 2T(\frac{n}{2}) + n$$

Here a = 2, b = 2 and m = 1, and f(n) = n.

Is
$$n \in O(n^{\log_b a - \epsilon}) = O(n^{\log_2 2 - \epsilon}) = O(n^{1 - \epsilon})$$
. No

Is
$$n \in \Theta(n^{\log_b a}) = \Theta(n^{\log_2 2}) = \Theta(n)$$
. Yes.

Therefore the case $T(n) \in \Theta(f(n) \log n)$ applies, $T(n) \in \Theta(n \log n)$

Use the general Master Theorem for the recurrence

$$T(n) = 6T(\frac{n}{4}) + n^2$$

Here a = 6, b = 4 and m = 2, and $f(n) = n^2$.

Is
$$n^2 \in O(n^{\log_b a - \epsilon}) = O(n^{\log_4 6 - \epsilon}) = O(n^{\approx 1.29 - \epsilon})$$
. No

Is
$$n^2 \in \Theta(n^{\log_b a}) = \Theta(n^{\log_4 6}) = \Theta(n^{\approx 1.29})$$
. No

Is $n^2 \in \Omega(n^{\log_b a}) = \Omega(n^{\log_4 6 + \epsilon})$. Yes. Does $af(n/b) < cf(n) = 6(\frac{n}{4})^2 < .9n^2$, it is true for any value of $n \ge 4$ and c = .9.

Therefore case $\Theta(f(n))$ applies, $T(n) \in \Theta(n^2)$

Use the general Master Theorem to give the exact order of the following recurrence

$$T(n) = 2T(\frac{n}{2}) + \log\log n$$

Here $f(n) = \log \log n$. $f(n) \in O(n^{\log_2 2 - \epsilon}) = O(n^{1 - \epsilon})$, because $\log \log n < \log n$, also $\log n$ grow slower than n^c for any value of c > 0, therefore $\log \log n \in O(n^{1 - \epsilon})$

 $f(n) \notin \Omega(n^{\log_b a + \epsilon})$ as we cannot bound $\log \log n$ below with $n^{1.\epsilon}$, therefore $f(n) \notin \Theta(n^{\log_2 2})$.

Therefore, as the case $f(n) \in O(n^{\log_2 2 - \epsilon})$ applies, $T(n) \in \Theta(n^{\log_b a}) = \Theta(n^{\log_2 2}) = \Theta(n)$

Use the general Master Theorem to give the exact order of the following recurrence

$$T(n) = 2T(n/4) + \sqrt{n}$$

Here $f(n) = \sqrt{n}$. Note that $\sqrt{n} = \sqrt[2]{n^1} = n^{\frac{1}{2}}$

Here a=2 and b=4. We want to know in which order $f(n)=\sqrt{n}$ is with respect to $n^{\log_b a}=n^{\log_4 2}$

It does happen that $n^{\log_4 2} = n^{\frac{1}{2}}$ since $\log_4 2 = \frac{\log_2 2}{\log_2 4} = \frac{1}{2}$

Therefore, $\sqrt{n} \in O(n^{\log_4 2})$ and $n^{\log_4 2} \in O(\sqrt{n})$, thus $\sqrt{n} \in \Theta(n^{\log_4 2})$

We conclude that $T(n) = \Theta(\sqrt{n} \log n)$

Exercises on heapsort

- 1. Convert the array A = [10, 26, 52, 76, 13, 8, 3, 33, 60, 42] into a maximum heap
- 2. Is this array [23, 17, 14, 6, 13, 10, 1, 5, 7, 12] a heap? If not make it a heap.
- 3. Run the algorithm BuildHeap(A) on the array A = [12, 28, 36, 1, 37, 13, 4, 25, 3]. Show each step of your work using the array representation of the modified heap
- 4. Heapsort A[12, 28, 4, 37]. Important, show each step of your work using the array representation
- 5. Heapsort A = [25, 67, 56, 32, 12, 96, 82, 44] (very long)

Exercises on heapsort continue

- 6. What are the minimum and maximum numbers of elements in a heap of height h?
- 7. Where in a heap might the smallest element reside?
- 8. Is an array that is in reverse sorted order a heap?
- 9. Using the example Insert(A,10) in your class notes, show the steps in the execution of Insert(A,3) on the priority queue A = [15, 13, 9, 5, 12, 8, 7, 4, 0, 6, 2, 1] implemented using a heap
- 10. Similarly to the previous question, show the steps in the execution of ExtractMax(A) on the priority queue
 - A = [15, 13, 9, 5, 12, 8, 7, 4, 0, 6, 2, 1] implemented using a heap

Exercises on heapsort continue

- 11. A *d*-ary heap is like a binary heap, but instead of 2 children, nodes have *d* children.
 - 11.1 Explain how would you represent a 3-ary heap in an array, i.e. give the formulas for Parent(i), Left(i) and Right(i)
 - 11.2 What is the height of a 3-ary heap of n elements?
 - 11.3 Sketch the idea of a heapify routine for a 3-ary heap
 - 11.4 Give an implementation of ExtractMax() for a priority queue based on a 3-ary heap
- 12. Show how to implement a regular FIFO queue using a "min"-priority queue
- 13. Show how to implement a stack using a "max"-priority queue

Exercises on heapsort continue

- 14. Insertion sort and merge sort are stable algorithms while heapsort and quicksort are not. Can you explain why this is so?
- 15. Run Heapify(A,3) on the array A = [27, 17, 3, 16, 13, 10, 1, 5, 7, 12, 4, 8, 9, 0]
- 16. Heapify(A, i) in the class notes is a recursive algorithm. Write an equivalent iterative algorithm.
- 17. Run Heapsort(A) on the the array A = [3, 15, 2, 29, 6, 14, 25, 7, 5]
- 18. What is the running time of *Heapsort* on an array *A* of length *n* that is sorted in decreasing order?

Exercises on solving recurrence relations

1. Give asymptotic upper and lower bounds for T(n) in each of the following recurrences. Assume that T(n) is constant for $n \le 2$. Make your bounds as tight as possible, and justify your answers

a)
$$T(n) = 2T(n/2) + n^4$$

b)
$$T(n) = T(7n/10) + n$$

c)
$$T(n) = 16T(n/4) + n^2$$

d)
$$T(n) = 7T(n/3) + n^2$$

e)
$$T(n) = 7T(n/2) + n^2$$

f)
$$T(n) = 3T(n/4) + \sqrt{n}$$

g)
$$T(n) = T(n-2) + n^2$$

h)
$$T(n) = 4T(n/3) + n \log n$$

i)
$$T(n) = 3T(n/3) + \frac{n}{\log n}$$

k)
$$T(n) = 4T(n/2) + n^2\sqrt{n}$$

I)
$$T(n) = 3T(n/3 - 2) + \frac{n}{2}$$

m)
$$T(n) = 2T(n/2) + \frac{n}{\log n}$$

n)
$$T(n) = \sqrt{n}T(\sqrt{n}) + n$$

o)
$$T(n) = T(n-2) + \log n$$
